# Analysis of Statistical Modeling Methods for Small-Volume Samples 

Popukaylo V.<br>T.G. Shevchenko Dniester State University<br>Tiraspol, Moldova<br>vsp.science@gmail.com

#### Abstract

There are offered some statistical modeling methods for small-volume samples on the base of passive observational study which may be used for getting multidimensional adequate mathematical models on samples of small volume.

Index Terms - statistical modeling, small-volume samples, passive observation, modeling of the technological process, point distribution method.

## I. Introduction

In the modern industry there are such productions which because of technological limitations cannot provide a sufficiently large sample volume, in accordance with the laws of experiment planning theory to get adequate mathematical model suitable for managing complex control object.

This state of things exists at many enterprises with smallscale production, as well as enterprises producing high-tech and expensive products.

Similar examples can be found in medicine, biology, economy and other branches of human activity.

In this paper we propose a method of multidimensional point distribution allowing to obtain adequate mathematical models of complex object-based multidimensional small samples.

To eliminate the loss of information when processing small samples is necessary to abandon groups of observations and to go to the methods of considering each individual realization as a distribution center of a virtual sample with the appropriate parameters.

The aim of this work is to compare mathematical models obtained after the analysis of the basic data and data obtained after application of multidimensional pointed distributions method.

## II. Research Methods

In the work "Small-volume samples" (by DV Gaskarov, V. Shapovalov) the specific methods principles of statistical small samples processing are most clearly articulated and substantiated. Development of this work led to the definition of the small volume samples upper range limit $\mathrm{n}=15$ [1], and to create a point distributions method (PDM) [2].

To eliminate the loss of information when processing small samples is necessary to abandon groups of observations and to go to the methods of considering each individual realization as
a distribution center of a virtual sample with the appropriate parameters [3]. These methods include PDM, using which each measurement is considered as a distribution center with the known law. The usage of PDM allows to obtain the accuracy of calculations corresponding to sample volume 3-5 times larger than the initial.

However, in real production a lot of factors affect the target function and required regression equation to be multidimensional. There are various methods for passive experiment tables processing, among which there is the method of least squares with pre-orthogonalization factors (MLSO) and the modified random balance method (MRBM) [4].

One of the oldest and most developed methods for passive data modeling is method of least squares (MLS) which is based on selection of equation of regression for the sum of squares of a difference between the equation and experimental data was the smallest of all possible. However, there is a problem when the recognition of any factor is insignificant, it is necessary to exclude it from consideration and to do all computing procedure from the very beginning. MLSO, which proposes to choose special system of linearly independent functions for each regression task, so that the normal equations matrix is single, became the solution of this problem [4]. In this case, there is no need to look for the inverse matrix, and it is possible to reject insignificant coefficients of regression without the others. The choice of function system is carried out with use of orthogonal polynoms of Chebyshev so that the $Y(X)$ curve decayed on the chosen system of functions in a row, $X k j$ which is quickly meeting in each point. Thus the system of functions has to be defined on that interval of values of the $X k j$ variable on which experimental points are located. However, MLS is sensitive to the order of sequence factors in order of importance, as well as increasing the number of factors and decrease the number of lines is much more complicated and increases the processing error.

Also one of the most known and most convenient methods of modeling of passive experiments is the random balance method(RBM). The essence of RBM is to construct a planning matrix with a random distribution of factor levels in the experiment on the matrix and in specific data processing experiment. Later this method has been developed to a modified random balance method (MRBM), which is complex and cumbersome graph-analytical procedure estimates the coefficients of the model is replaced by easier analytical procedure. This method has a high resolution (the ability to
allocate strongly influencing factors), and low sensitivity (i.e., the ability to allocate significant model parameters which characterize the factors that have a relatively weak effect) [4]. However, as the modified random balance method (MRBM) is the eliminating method, so its application to small selections is not possible.

For solving this problem, below is shown a method that combines the ideas of two other methods. The first part of the calculations performed by the method of point distributions, treating each factor by the initial sample point distributions and knowing the nature of the distribution law may artificially increase the sample size in order to be able to use one of the methods for obtaining adequate mathematical models for passive data. Joining individual factor samples in a single multi-dimensional large sample volume occurs in the lines with the highest level of offensive probability density and with simultaneous cutting off of all incomplete lines.

There was thus developed a fundamentally new multidimensional distributions point method (MSPM) to obtain adequate mathematical models of complex multidimensional object based on the initial samples of small volume.

Algorithm:

1. A correlation analysis, the purpose of which is to find highly related factors.
2. By means of MSP for all $X i$ and $Y$ to build tables for calculating non-normalized probability densities in the virtual domain.
3. For each line $l$ of the initial experimental data table to construct a virtual data table, in which to simultaneously bring in the values of two Xij columns from corresponding table of non-normalized probability densities and Xil column. Alignment (joining) pairs of columns Xij and Xil (and) Yj and $Y l$ should occur at the maximum probability density level.
4. From all tables found in the preceding paragraph of this algorithm is filled with rows and all columns indicating the non-normalized probability density are not completely erased. The joining of edited tables occurs in numerical order of input data table rows. The received virtual data table is $15-20$ times longer than initial data table, it allows to achieve the bigger accuracy and reliability during its processing.
5. According to the table of complete virtual sample we determine coefficients of correlation of all factors and output size by the principle "everyone with everyone", for the detailed analysis we use correlation pleiades method in conjunction with an expert weighting coefficients of importance method.
6. According to the received table we make mathematical model by methods of passive experiment, such as: the modified random balance method, the smallest squares method with preorthogonalization of factors, or the combined method.

Thus, we can construct a mathematical model appropriate for small volume sample, even if the initial small sample was supersaturated up.

## III. Results And Discussion

Let's take as a result from the production $\mathrm{n}=5$ produc units (parties) the following numerical values of control parameters ( Xi - the parameters controlled during technological process; Y

- output quality indicator of a product. All names of dimensions for simplicity are ammited)

TABLE I. Table Of Initial Experimental Data

| Number <br> of <br> product | Factors $\boldsymbol{X}_{\boldsymbol{i}}$ |  |  |
| :---: | :---: | :---: | :---: |
|  |  |  |  |
| 1 | $\boldsymbol{X}_{\text {If }}$ | $\boldsymbol{X}_{2 \boldsymbol{f}}$ | value, $\boldsymbol{Y}$ |
| 2 | 0,549 | 2,1682 | 72,22 |
| 3 | 0,478 | 2,1371 | 71,65 |
| 4 | 0,485 | 2,8629 | 46,65 |
| 5 | 0,441 | 2,4838 | 48,85 |
| 6 | 0,397 | 2,0652 | 43,87 |
| 7 | 0,257 | 2,0801 | 60,63 |
| 8 | 0,342 | 2,1557 | 80,84 |

To handle such a table of random balance modified method is not possible because of the small row number, so use the method of least squares with pre-orthogonalization factor that is less sensitive to this factor.

As a result of calculations the adequate model was received:

$$
\begin{aligned}
Y=-2297 & +1193,2 X_{l}+1839,4 X_{2}-744,38 X_{1} X_{2}+ \\
& +475,15 X_{1}^{2}-325,63 X_{2}^{2}
\end{aligned}
$$

The adequacy dispersion of this model $=139.8398$
The average weighted dispersion $=46.51099$
Fisher criterion $\mathrm{Fr}=3.007$
When the tabulated value is $\mathrm{Ft}=3.87$
Thus the resulting model is adequate, but it has a great adequacy dispersion and calculated value of the Fisher criterion.

We try to apply this multidimensional point distributions method for a better mathematical model of researched process. To do this using the point distributions method for all $X i$ and $Y$ we construct a table for calculating non-normalized probability densities in the virtual domain. As an example, here is presented a calculation for $X_{I}$ factor.

TABLE II. Table Probability Densities

|  |  | $\boldsymbol{X}_{\boldsymbol{l f}}$ |  |  |  |  |  |  |  |

| 30 | 0,705 | 0,07 |  | 0,35 | 0,01 |  |  |  |  |

For every line $f$ of table of initial experimental data we construct the tables of virtual data in which we simultaneously bring in the values of two $X_{i j}$ columns from the corresponding table of unrationed density probabilities(similar to Table II) and the $X_{i f}$ column. Alignment (joining) pairs of columns $X_{\mathrm{ij}}$ and $X_{i l}$ (and) $Y_{j}$ and $Y_{l}$ should occur at the maximum probability density level. The joining of edited tables occurs in numerical order table rows of input data. The result is a complete virtual sample that is presented in Table III.

TABLE III. Table Of Virtual Sample

Chisinau, 20-23 May 2015

As according to the experiment planning theory only independent factors are liable to modeling, at the next step according to full of virtual sample table we determine the correlation coefficients of all the factors and all the output value according to the principle "everyone with everyone". The results are put in Table IV.

If a detailed analysis of coefficient pair correlation table is needed, it is recommended to use the correlation pleiades method [5] combined with an expert method of weighting importance coefficients [4].

TABLE IV. Table Of Correlation Coefficients

|  | $\boldsymbol{X}_{\boldsymbol{I}}$ | $\boldsymbol{X}_{\mathbf{2}}$ | $\boldsymbol{Y}$ |
| :---: | :---: | :---: | :---: |
| $\boldsymbol{X}_{\boldsymbol{I}}$ | 1 | 0,441 | 0,448 |
| $\boldsymbol{X}_{\boldsymbol{2}}$ | 0,441 | 1 | 0,551 |
| $\boldsymbol{Y}$ | 0,448 | 0,551 | 1 |

Having analyzed the correlation matrix we conclude that the factors are independent and we start modeling through one of the methods, which helps to receive adequate mathematical model by passive data.

Applying the method of least squares with preorthogonalization factors we were not able to build adequate mathematical model.

Applying the modified method of random balance was formed following adequate mathematical model:

$$
Y=62,005+6,23 X_{1}+8,26 X_{2}+9,17 X_{1} X_{2}
$$

(with numerical value codes $-1 \leq X_{i} \leq+1$ ).
The adequacy dispersion of this model $=44,83844$

The average weighted dispersion $=140,9533$
Fisher criterion $\mathrm{Fr}=0,3181085$ when the tabulated value is $\mathrm{Ft}=1,5$

The received model has a lower dispersion adequacy and best calculated value of the Fisher criterion than the initial, and thus can be considered more operable.

## IV. CONCLUSIONS

1. Suggested a fundamentally new method of constructing adequate multidimensional models by small volume samples.
2. Possibility of receiving more efficient model at application of a method of multidimensional pointed distributions is proved.
3. It is required the expansion of this method to different character data and for solving various problems.
